ACKNOWLEDGEMENTS

Recognition is due to the many people without whom I would not have been able to accomplish this task. I would like to extend a very heart felt appreciation and thanks to my advisor, Dr Elrod, for his patience, positive support and long hours; to Dr Richard Rivir of the Aero Propulsion Laboratory for his timely assistance and advice; to Jay Anderson, Leroy Cannon and Nicholas Yardich for all their technical help and patience; to Joe Hofle for fabrication support and to my classmates for their moral support even though they too were very busy. Lastly I would like to give a very special thanks and much love to my husband, Jim, for his love, confidence, and cheerful support during this endeavor.

Denise C. Oka

| μ_{mean} | absolute viscosity at the mean fluid temperature, lbm/ft sec |
| π | ratio of circle's circumference to its diameter, an irrational constant, $\pi = 3.141593...$ |

ABSTRACT

↓
An investigation was made of the possibility of developing a single calibration equation that would be applicable to a wide range of temperatures (68 F to 250 F), velocities (150 to 800 ft/sec), and pressures (15 to 33 psia). A platinum hot-film, with a high enough operating temperature to provide good sensitivity to velocity, was calibrated at seven different temperature/pressure conditions. The data was used to calculate velocity, Reynolds number and Nusselt number, and a linear least squares curve fit was applied to the data as a function of Reynolds number raised to an exponent and as a function of Nusselt number times a load factor raised to an exponent. The exponents were chosen, through an iterative process, to provide the best agreement between the data and the curve fit equation. The results indicate that as the range of conditions is allowed to increase so does the error between measured velocity and velocity derived from the calibration equation. The least deviation in velocities occurred for curve fits of individual sets of data giving an average of 0.8% to 2.5% difference. When several different temperature or several different pressure curves were curve fit as a single curve the error could be minimized to 2.5% to 3.1% if the velocity range was narrowed to 300 to 700 ft/sec.

CALIBRATION OF A HOT-WIRE/HOT-FILM ANEMOMETER
OVER A RANGE OF
TEMPERATURES, VELOCITIES, AND PRESSURES

I. Introduction

Historically, most hot-wire/hot-film applications and therefore calibrations have been at ambient pressure, in incompressible flow and at relatively low temperatures (ambient to about 150 F). Calibrating under these conditions and over a narrow range of temperatures makes it fairly easy to collapse calibration data to a single curve. However, applications exist, such as in shock tube studies, where it would be desirable to have a single calibration curve that could be applied to a wider range of temperatures, pressures, and velocities and where both incompressible and compressible flow could be accounted for. Little work has been done in this area, with the most notable being McQueen's effort [10]. His work was at ambient pressure for temperatures of 74 F, 175 F and 275 F and velocities from 300 to 900 feet per second. He found that the hot-wire he used (a TSI T1.5 sensor) lacked the sensitivity needed at the higher velocities and temperatures. The best sensitivity achieved was .222 millivolts for each foot per second of velocity. To achieve this the wire had to be operated at or above the maximum recommended operating temperature causing the wire to experience structural and thermal problems.

Objective and Scope

The purpose of this thesis was to look at the feasibility of achieving a single hot-wire/hot-film calibration curve for a wide range of temperatures (68 F to 250 F), velocities (150 to 800 ft/sec), and pressures (15 to 33 psia). Fifteen psia was chosen instead of ambient pressure because this allowed comparison of test data at a common pressure instead of one which changed with the conditions of the day. A hot-film sensor was used so that an operating temperature higher than McQueen's could be achieved. This was expected to enable greater sensitivity and thereby overcome some of the difficulties that he encountered. Fig.1 shows the specific temperature/pressure combinations that were examined where T_{o1} to T_{o5} and P_1 to P_3 are the total temperatures and static pressures, respectively.

| | | |
|--------------------------------|-------------------------|---|
| $T_{o1} = 68^{\circ}\text{F}$ | $P_1 = 15 \text{ psia}$ | $\text{Vel} = 150 \text{ to } 800 \text{ ft/sec}$ |

| $T_{o5} = 250^{\circ}\text{F}$ | | |

Figure 1: Calibration Conditions

II. Experimental Apparatus

This chapter describes the major pieces of equipment used for this investigation, including the data acquisition system. Some components of the experimental set up were chosen through an evolutionary process and in these cases a synopsis of events is presented.

Calibrator

A schematic of the calibrator used for hot-wire calibration is shown in Fig.2. It was modeled after a TSI Model 1125 calibrator and designed and fabricated by AFWAL's Aero Propulsion Laboratory, Wright-Patterson Air Force Base, Ohio. It was modified by the AFIT Model Shop to enable it to withstand the higher internal pressures of the experiment.

Air was brought in from the inhouse compressors and passed through three filters to remove oil, water, and particulates. At the inlet to the calibrator, the central core of the airflow was dispersed by a very fine mesh screen. The air was heated by four resistance heaters, which were controlled by a Variac autotransformer. The calibrator body was wrapped in fiberglass insulation to help retain heat and reduce temperature gradients along its steel body. The air flow was essentially stagnant until passing through the one-eighth inch diameter nozzle just upstream of the sensor. This particular nozzle diameter was chosen after it had been experimentally determined that a larger nozzle diameter increased the air flow rate beyond the calibrator's ability to heat it for the desired temperature range.

Figure 2: Hot-Wire/Hot-Film Calibrator

Measurement of total temperature and pressure in the chamber upstream of the nozzle was made using two bare wire copper-constantan thermocouples insulated from the calibrator body by ceramic tubing and a 0 to 50 psig pressure transducer, respectively. There was also a second pressure transducer reading taken near the sensor to give static pressure downstream of the nozzle. Air flow rate and static pressure at the sensor were controlled by manipulation of the two valves shown in Fig.2.

Hot-Wire/Hot-Film Anemometer and Sensor

The hot-wire/hot-film measurement system used was a Thermo-Systems, Inc. (TSI) Model 150 Anemometer housed in the TSI IFA-100 Intelligent Flow Analyzer.

The choice of sensor was influenced by the results of McQueen's work [10]. He had used a single tungsten hot-wire with a recommended maximum operating temperature of 300 C (572 F). McQueen operated the wire near this maximum temperature and achieved only marginal sensitivity at higher velocities and temperatures. He also had difficulty not exceeding the structural and thermal limits of the hot-wire.

In order for the sensor to be sensitive to velocity, TSI recommends that the wire temperature be at least 200 C (392 F) greater than the temperature of the fluid in which it is immersed [2]. Because of this and McQueen's observations, the first choice for a sensor was TSI's 1220 PI2.5. This is a high temperature platinum-iridium hot-wire with a maximum operating temperature of 800 C (1472 F) and a diameter of .00025 inches.

Four attempts at calibration were made with the PI2.5, and each time the sensor's wire broke. All breakage occurred with the wires cold, i.e. with no current being applied.

The appearance of the first broken wire indicated that particulate matter had impacted against it (Fig.3). Examination of the probe under magnification revealed small black particles on the wire. It was also noted that part of the broken wire was bent downstream in such a manner as to indicate it had been struck by an object. The calibrator was dismantled, and charred gasket material was seen inside the calibrator assembly. Apparently the calibrator had become too hot for the gasket material causing it to char. It is possible that some of this charred material broke loose and struck the wire. The system was cleaned, the maximum fluid temperature limited to prevent charring and a second PI2.5 wire tried. This too broke, and upon examination under magnification some very fine droplets could be seen on the wire. Inside the calibrator, an oil film was visible in the chamber above the nozzle. The system was again cleaned and filters for oil and particles placed in the air line. The third PI2.5 wire was installed and the heating process started. Before operating temperature was reached, this wire also broke. Water was found in the particle filter and in the elbow and pressure line just below the inlet valve. The inlet valve and elbow were originally located directly below the dispersion screen identified by #4 in Fig.2. It appeared that the pressure and temperature drop caused by the air expanding across the valve was causing water vapor to condense and accumulate. Because of this, the valve location was moved and a dump tube added to allow air expansion to occur prior to the filters (Fig.2, #3 and #16). The particle filter was replaced with a

- a) Sharp bend in broken wire; particulate viewed under microscope indicates wire was impacted by a relatively large particle.
- b) Wire not bent at all but is separated at the center; moisture appears to be on wire, cause of breakage unknown.
- c) Very slight vertical separation between the broken ends; no visible cause of breakage.

Figure 3: Appearance of the 1st Three Broken P12.5 Hot-Wires

dual filter system which removed both water and particles (Fig.2, #17 and #18). A fine wire mesh screen was placed as shown in Fig.2, #19, to prevent very small particles from reaching the wire. These measures taken to clean the supplied air were all that could be done with the time and equipment available. A fourth hot wire was installed, but once again it failed. No cause was visibly identifiable, and, according to the wire's specifications in Reference [13], none of its limits had been exceeded. Except in the case of the first wire, fluid temperature never exceeded about 350 F, ranging between 120 F and 350 F. The maximum allowable fluid temperature for this wire is 1382 F. Velocity was about 300 ft/sec, well below its 1000 ft/sec maximum. Because of the extreme frailty of the PI2.5 hot-wires, other options were reviewed that would still provide the desired higher operating temperature. Platinum hot-films were the next logical choice with a maximum operating temperature of 425 C (797 F). Those available were not designed for high temperature fluids so it was decided to keep fluid temperature less than 250 F to prevent structural problems. This limitation allowed the hot-film to be operated at 645 F providing the temperature difference recommended for good sensitivity and adding a safety margin by staying below the maximum operating temperature. The cylindrically shaped hot-film was chosen over the wedge or cone because its heat transfer equations for data reduction are simpler and well documented.

The particular sensor model chosen was the TSI 1241-10, a dual sensor, end flow, X-film. McQueen had done some work with TSI's 1214-10, a single straight sensor hot-film, and noted that in shock tube applications vibrations occurred. It was hoped that if this sensor were

used in a shock tube, the load caused by shock passage would be less due to the sensor's angle to the flow and possibly prevent vibration.

Data Acquisition System

Initially data was taken manually using pressure gages to display gage pressure readings, thermocouples attached to Omega Digicators to give temperature directly in F (or C), and the IFA-100 to read the voltage corresponding to a given velocity and temperature. The source pressure could not be held constant, cycling from a maximum value to some value three to five psi less and then back to a maximum. One instrument reading would be taken each time the source pressure reached its maximum value. This was an extremely time consuming process and provided instrument readings that were not all necessarily at the same source pressure for a given data point.

Automation was the next step. An HP-3052A data acquisition system (Fig.4) became available that was already configured, with software, for hot-wire calibration. With a few minor changes to equipment and modification of the controlling data acquisition program, this system enabled each set of data to be taken automatically and quickly enough to be essentially at the same source pressure. The pressure gages were replaced with pressure transducers and signal conditioners. An existing thermocouple was used for ambient temperature readings. An oscilloscope was used in conjunction with the IFA-100's built-in signal generator to maximize the frequency response of each sensor of the dual sensor hot-film.

All pressure transducer, thermocouple and hot-film sensor signals were brought into the system's voltmeter and processed by the HP-9845

Figure 4: HP-3052A Data Acquisition System

computer. Pressure transducer voltages were converted to gage pressures using predetermined calibration equations. Thermocouple signals were converted to temperatures using an existing HP subroutine. The hot-film sensor voltages were used directly in the heat transfer equations. The data acquisition program enabled the gathered data and some reduced results to be tabulated and plotted.

Pressure Transducers/Gages

Three gage calibrated pressure transducers were used to measure static pressure by the sensor, total pressure in the calibrator body upstream of the nozzle, and the source pressure. These gage pressures were converted to absolute pressure by adding the standard barometric pressure ($P_{amb} = 14.696$ psia) [6] to the gage value.

Each transducer was connected to a separate Endevco signal conditioner and all were powered by the same Endevco power supply. Each transducer, its corresponding signal conditioner, and the power supply was calibrated as a single unit using the MKS Portable Vacuum Standard and an HP3438A digital multimeter. The MKS controlled and displayed the pressure being applied to the transducer and the multimeter displayed the transducer's corresponding voltage. The calibrator static and total pressure transducers were calibrated from 0 psig to 41 psig in 5 psi increments. The source pressure transducer was calibrated from 0 to 96 psig in 5-10 psi increments. Straight line equations were calculated for each set of data and were used as the calibration equations in the data reduction program.

The pressure gages that had been part of the manual data acquisition system were left attached to provide a quick look reference for the operator. A list of all equipment used is provided in Appendix C.

III. Theory of Hot-Wire Operation

In the following discussion the term hot-wire will be synonymous with the term hot-film unless otherwise stated.

Hot-wire anemometers are often used to measure fluid velocity and turbulence. The anemometer wire is heated by passing an electric current through it, and then the heat lost by the sensor (wire) to the fluid is measured. The two methods of operating a hot-wire anemometer are the constant current method and the constant temperature method. Of these, the most common (and the one used in this study) is the constant temperature method. This method uses a feedback circuit incorporated into a Wheatstone bridge to maintain the sensor at a constant operating temperature. The amplifier senses changes in voltage due to changes in wire resistance and increases or decreases the current as needed to keep wire resistance and therefore temperature constant.

The anemometer output for the constant temperature system is the voltage output of the amplifier. This voltage is directly proportional to current ($V=IR$) because resistance is a constant. Note too that the square of this voltage is directly proportional to the heat transfer, Q , from the wire to the fluid since the heat transfer equals the electrical power, P , into the wire [2,4].

$$Q = P = I^2 R = V^2 / R \quad (1)$$

According to many sources, including Bradshaw [1], heat is transferred out of the wire by radiation, buoyant convection, conduction to

the wire's end supports and forced convection due to fluid flow. For the typical wire (and cylindrical hot film), radiation heat loss is only about 0.1% of the input energy and is negligible unless the flow density is very low. Buoyant convection is important only at very low speeds and can be neglected for a typical wire when fluid speeds are greater than 5 cm/sec. For this study both of these sources of heat loss were negligible. Conduction to the supports and forced convection were the main sources of heat loss. Equations relating to the anemometer and heat transfer will be discussed in the section on data reduction.

For more detailed information on the evolution of hot-wire anemometry and its varied uses refer to Reference [5], which provides a comprehensive bibliography of the thermal anemometry work accomplished since 1817.

IV. Experimental Procedure

The first section of this chapter provides an overview of procedures and calculations that had to be accomplished prior to gathering calibration data. The second section describes the data taking process and factors that influenced it.

Pre-Calibration

Prior to calibration the orientation of the sensors' axes to one another was determined to be 90 degrees. The probe was positioned such that flow impinged at 45 degrees to the sensors' axes allowing each sensor to feel the velocity equally (Fig.6). This provided a redundancy factor in that had one sensor broken, the remaining sensor would still have provided enough information to determine flow velocity.

Next the total hardware resistance, eqn.(2), was found and entered into the anemometer's memory [13].

$$R_{hw} = R_{cable} + R_{ps} + R_{int} \quad (2)$$

where:

R_{hw} = total hardware resistance, ohms

$R_{cable} + R_{ps}$ = cable and probe support resistance found
using the anemometer and shorting the probe
support, ohms

R_{int} = internal resistance of all portions of the
probe (Fig.5) except the sensors, ohms;
provided by the manufacturer.

- a) pins to insert into probe support
- b) probe body
- c) sensor supports
- d) X-film sensor

Figure 5: Probe Schematic

Figure 6: Position of Sensor Relative to the Nozzle and Flow

The anemometer subtracts this value from all subsequent resistance measurements so that actual sensor resistance is measured as a function of fluid temperature. This feature enabled the relationship of cold resistance to fluid temperature to be determined, where cold resistance is defined as the sensor resistance measured when the sensor is 1/16 of an inch downstream of the calibrator nozzle, flow is less than 100 ft/sec and no current is passing through the wire. The flow temperature was varied and a resistance measurement taken at each new temperature. Since no current was heating the wire, the fluid temperature was the sensor temperature. This data resulted in a linear equation [2,13] for each sensor of the form

$$R_C = R_O + (\alpha R_C) T_C \quad (3)$$

where:

T_C = fluid temperature, F

R_C = sensor resistance at T_C , ohms

R_O = sensor resistance when $T_C = 0$ F, ohms

αR_C = slope, ohms/F

= temperature coefficient of resistance times
resistance at temperature T_C

Operating resistance was calculated from eqn.(4) and input into the anemometer which used it to maintain sensor operating temperature [13].

$$R_{op} = R_C + \alpha R_C (T_{op} - T_C) \quad (4)$$

where:

T_{op} = sensor operating temperature, F

R_{op} = sensor operating resistance for a given T_{op} , ohms

T_c = arbitrarily chosen value of fluid temperature, F

R_c = cold resistance for chosen value of T_c , ohms;

calculated from eqn.(2)

αR_c = slope corresponding to relevant cold resistance

vs. temperature equation, ohms/F

Note that, because of the relationship established between cold resistance and fluid temperature (eqn.3), for a given operating temperature the operating resistance will be a constant regardless of the value of T_c chosen.

Data Acquisition

Calibration was accomplished using the HP-3052A Data Acquisition System and its controlling hot-wire calibration program. The program monitored the voltage signals from the pressure transducers, thermocouples and the anemometer and converted the appropriate signals to psia and F. Velocity at the sensor and pressure and temperature up and downstream of the sensor were displayed for operator use. When the desired conditions were observed, a data point could be taken, recorded and stored. The program automatically stored total temperature (degrees F) and total, static, and ambient pressure values (psia), as well as anemometer voltages for each data point.

Data for seven calibration curves were gathered. Each curve represented a specific temperature/pressure combination over a range of

velocities (Fig.1). Ten to thirteen data points were taken for each curve. For each data point, the static pressure was kept within ± 0.5 psi of the desired value, the top thermocouple within ± 1 F of the calibration temperature and the two thermocouples within ± 2 F of each other. This last condition was difficult to achieve at higher velocities and increased temperatures. The difference between the thermocouple readings was as much as 3 to 17 F even after hours of waiting for equilibrium to become established. After discussing this phenomenon with Dr. Rivir [12], it was decided that only the top thermocouple should be used to determine temperature since it was likely that the bottom thermocouple was in either a stagnated or recirculating region.

Calibration of a single temperature/pressure curve generally took 8 to 10 hours where 2 to 3 hours were spent initially bringing the system up to temperature. Any given data point took only seconds to record but achieving the proper conditions could take 10 to 40 minutes of adjusting and waiting for temperatures to equilibrate. Because of calibrator design, the sensor was exposed to the flow for this entire operating time.

V. Data Reduction

The goal of data reduction for this investigation was to generate a linear equation, of the form of eqn.(5), which fit single or multiple sets of data with negligible error. The general calibration equation used to accomplish this was taken from Collis and Williams [3] and Bradshaw [1] and is shown in eqn.(6). The temperature load factor is applied to the Nusselt number to compensate for the effect of using a mean temperature to calculate fluid properties and to aid in the collapsing of data [1,3]. Pressure and pressure/temperature load factors were also investigated for use with data that covered a range of pressures.

$$y = A + Bx \quad (5)$$

$$Nu * Load Factor^{X_o} = A + B * Re^{X_n} \quad (6)$$

where:

$$Nu * Load Factor^{X_o} = y\text{-coordinate}$$

$$Re^{X_n} = x\text{-coordinate}$$

$$A = y\text{-intercept}$$

$$B = \text{Slope}$$

$$X_n = \text{Reynolds number exponent}$$

$$X_o = \text{Load factor exponent}$$

$$\text{Load Factor} = (T_{\text{mean}}/T_f) \quad (7a)$$

$$\text{or} = (P_s/P_{\text{amb}}) \quad (7b)$$

$$\text{or} = (P_s/P_{\text{amb}} * T_f/T_{\text{mean}}) \quad (7c)$$

T_{mean}/T_f = ratio of mean fluid temperature to
measured fluid temperature, R/R

P_s/P_{amb} = ratio of static pressure at sensor
to ambient pressure, psia/psia

The constants X_o , X_n , A and B were found through an iterative process. Initially X_o and X_n were chosen to be $X_o = -.17$ and $X_n = .45$ or $.51$, the values recommended by Collis and Williams [3]. Then a least squares curve fitting routine was applied to the x, y coordinates, Re^{X_n} and $Nu * \text{Load Factor}^{X_o}$, respectively, to determine A, B and the values of standard error and the percent differences between derived and input values of x and y. X_o and X_n were varied to minimize the standard error and the percent differences. Once the curve fit error was minimized, the resulting values of A, B, X_o , X_n and both the input x and y coordinates and the derived x and y coordinates were tabulated (see Appendix B). Also tabulated were the measured and derived velocities and the percent difference (eqn.8) between the two. The percent difference was used to determine how well the data agreed with the curve fit.

$$\% \text{ diff} = (u_{\text{derived}} - u_{\text{meas}}) / u_{\text{meas}} * 100 \quad (8)$$

Measured velocity is given by eqn.(10) and derived velocity is given by

$$u_{\text{derived}} = (Re_{CF} * \mu_{\text{mean}}) / (\rho * d * 0.707) \quad (9)$$

where:

Re_{CF} = Reynolds number derived from the curve fit equation,

eqn.(6)

$$= ((Nu * Load Factor^{X_0} - A)/B)^{1/X_n}$$

These calculations were done for both sensors but only the results relative to sensor 1 are presented in the text since behavior of the two sensors was very similar. Appendix B provides tabulated data for the all graphs displayed in this report and a sample of sensor 2's data for comparison.

To achieve the data reduction described above, the measured temperatures, pressures and voltages had to be converted to more meaningful fluid properties such as velocity, Reynolds number and Nusselt number. Presented below are the equations used to calculate fluid properties and their key variables. Based on data presented in Keenan and Kayes' Gas Tables [9], G , c_p , and R were assumed constant for air over the range of temperatures used in this investigation.

Velocity

It was desirable to know the velocity at the sensor and to use it to calculate Re and Nu . The velocity was assumed equal to the nozzle exit velocity and was derived using eqn.(10) and the measured total temperature and pressure ratio [7]. Because of its positioning (Fig.6), the hot-film senses only the normal component of this velocity.

$$u = ((2/f)RT_0(1-(P_s/P_0)^f))^{0.5} \quad (10)$$

where:

u = velocity, ft/sec

$f = (G - 1)/G$

$G = \text{gamma} = 1.397$

R = gas constant for air = $1716 \text{ ft}^2/\text{sec}^2 \text{ R}$

T_o = total temperature at sensor (top thermocouple), R

P_s/P_o = static to total pressure ratio across the nozzle

Static Temperature

Static temperature was needed to calculate adiabatic wall temperature and therefore Nu. Using total temperature and velocity, static temperature at the sensor is given by [7]

$$T_s = T_o - (u^2/(2c_p)) \quad (11)$$

where:

T_s = static temperature, R

c_p = specific heat at constant pressure

= $6057.47 \text{ ft}^2/\text{sec}^2 \text{ R}$

Recovery Factor

Recovery factor (eqn.12) is a measure of how closely adiabatic wall temperature approaches free stream stagnation temperature [7].

$$r_c = (T_{aw} - T_s)/(T_o - T_s) \quad (12)$$

An approximate value of r_c can be calculated and used to determine adiabatic wall temperature. To determine this approximate value, an

adiabatic wall temperature based on adiabatic cold resistance, R_{ad} , (eqn.13) and the T_s and T_o corresponding to R_{ad} are substituted into eqn.(12) [14,12]. Adiabatic cold resistance is defined as the cold resistance of the wire measured at calibration temperature but with flow velocity greater than 100 ft/sec.

$$T_{aw}' = (R_{ad} - R_c) / (\alpha R_c) + T_c \quad (13)$$

where:

T_{aw}' = adiabatic wall temperature, F

R_{ad} = adiabatic cold resistance, ohms

T_c = arbitrarily chosen value of fluid temperature, F

R_c and αR_c based on eqn.(3) for the chosen T_c

The original data acquisition program required a one time calculation of recovery factor at a desired test velocity and temperature. Test temperature was the calibration temperature, a constant, but velocity could only be an arbitrarily chosen constant, since calibration covered a range of velocities. Because of this, program users chose a velocity somewhere in the middle of the range of velocities and calculated recovery factor there.

For a laminar compressible boundary layer, r_c should be approximately equal to the square root of Prandtl number, about 0.84 for air up to moderately high temperatures [7]. When calculated for this investigation the values were erratic. The equation for recovery factor shows two possible places for error to occur. One is in the calculation of T_{aw}' which is a function of cold resistance and the other is in the measurement of T_o . Total temperature could not be readily doublechecked

because of the system design, but the relationship of cold resistance to temperature could. Upon re-examination it was found that the slope of eqn.(3) had increased approximately 3% and the y-intercept had decreased approximately 3%. This change had occurred over a period of about a month. The impact of an incorrect slope on the calculation of T_{aw}' was significant, often causing the adiabatic wall temperature to be less than the static temperature and therefore adversely affecting the calculation of recovery factor. Because of this problem Dr. Rivir [12] recommended the following procedure:

- 1) calculate recovery factor at room temperature so as to minimize the possibility of temperature being an unknown. The assumption here is that recovery factor does not change significantly with temperature,
- 2) measure cold resistance "real time"; meaning choose T_c of eqn.(13) to be room temperature and use the anemometer to measure the cold resistance with flow less than 100 ft/sec. Use these values in the calculation of T_{aw}' along with the newly found value of the slope,
- 3) measure R_{ad} at a series of velocities and calculate T_{aw}' and recovery factor for each,
- 4) take the average of the recovery factor.

This average value of recovery factor was used in the data reduction program.

Since the cold resistance versus temperature relationship (eqn.3) could effect the values of operating resistance (eqn.4) and therefore Nusselt number (eqn.19), some calculations were made to determine the impact. R_c was calculated using the old and new versions of eqn.(3) and then values of R_{op} and Nu were calculated. The results indicated a negligible impact on all three quantities, showing a 1.1% and 0.9%

difference in R_c , a 0.3% and 0.1% difference in R_{op} , and a 0% and 0.012% change in Nusselt number for sensors 1 and 2, respectively.

Adiabatic Wall Temperature

Eqn.(14) [8] was used to calculate the adiabatic wall temperature of the hot-film with no current applied.

$$T_{aw} = (r_c * u^2) / 2c_p + T_s \quad (14)$$

where:

T_{aw} = adiabatic wall temperature, R

u = velocity, ft/sec

Fluid Properties/Mean Fluid Temperature

Since there was a large difference between film and fluid temperatures, the fluid properties, density, thermal conductivity, and absolute viscosity, were calculated as a function of the mean fluid temperature [8] which is given by eqn.(15).

$$T_{mean} = (T_{op} + T_s) / 2 + .22(T_{aw} - T_s) \quad (15)$$

where:

T_{mean} = mean fluid temperature, R

T_{op} = operating temperature of the wire, R

Nusselt Number

The Nusselt number is a dimensionless quantity representing heat transfer from the film due to flow over the sensor [4,8]. It is defined as:

$$Nu = hd/k \quad (16)$$

Since Nusselt number is also a function of Re, M and Pr, it is possible through calibration to relate heat transfer, as a function of Nusselt number, to the local velocity at the sensor as a function of Reynolds number. For a constant temperature anemometer, heat transfer equals the square of the voltage across the hot-film divided by hot-film operating resistance [4]:

$$Q = V_w^2 / R_{op} = \frac{(\text{Volts} * R_{op})^2}{(R_{op} + R_{bridge} + R_{hw})^2} / R_{op} \quad (17)$$

The convective heat transfer is related to Q by [7]:

$$Q = hfdL(T_{op} - T_f) = V_w^2 / R_{op} \quad (18)$$

Manipulating equations (16, 17, and 18), Nusselt number can be written as:

$$Nu = \frac{\text{Volts}^2 * R_{op}}{f * L * K_{mean} (R_{op} + R_{bridge} + R_{hw})^2 (T_{op} - T_{aw})} \quad (19)$$

where:

Volts = anemometer bridge voltage

R_{op} = operating resistance of the sensor, ohms

R_{hw} = resistance of the hardware, ohms

R_{bridge} = 10 ohms = IFA-100 bridge resistance

L = length of hot-film, ft

K_{mean} = thermal conductivity at the mean fluid
temperature, volts²/(ohms ft R)

Reynolds Number

$$Re = (\rho * u_{\perp} * d) / \mu_{mean} \quad (20)$$

where:

ρ = density at the mean fluid temperature
and static pressure, lbm/ft³

d = diameter of hot-film, ft

μ_{mean} = absolute viscosity at the mean fluid
temperature, lbm/(ft sec)

VI. Results and Discussion

This section presents the results of data reduction for single, multiple, and modified data sets. It also provides a comparison of the results of these groupings.

Individual Data Sets (DS)

Each of the seven data sets was individually curve fit to provide a standard against which to compare the multiple data set curve fits. Figures 7 to 13 represent the best curve fit to each data set where the general calibration equation was

$$Nu(T_{\text{mean}}/T_f)^{X_o} = A + B * Re^{X_n} \quad (6)$$

The corresponding exponents, slope and y-intercept for each data set's calibration equation are presented in Table I. Table I also gives the resulting average percent difference in velocity. Velocity percent differences for each data point are provided in Appendix B. The very small deviations shown by the average percent difference indicate good agreement between the data and the derived calibration equation. This is the kind of agreement desired when collapsing data for varied conditions to a single curve. More than one value of average percent difference is shown for DS4, DS6 and DS7. In the case of DS4 the second value represents only the data marked by the circles on Fig.10. Difficulties in achieving the proper calibration temperature caused the omitted points, marked with triangles, to be recorded 3 to 4 hours later. There is a

noticeable change in slope of these later test points which raises the question as to whether this data should be considered separately. For DS6 and DS7 each had one point that was significantly different from the others. For DS6, it was at the low end velocity and for DS7 it was at the high end velocity which implies they may have been poorly taken data points. Results from using the modified data show improved values of the velocity average percent difference.

Combined Data Sets

To attempt the collapse of several data sets to a single curve, the individual data was divided into 2 groups. The first group, DS123, consisted of data from calibration runs 1, 2, and 3 where temperature was 120 F and static pressure varied. The second group, DS14567, contained data from calibration runs 1, 4, 5, 6, and 7 where static pressure was 15 psia and temperature varied.

DS123

Since pressure was a variable for DS123, the effect of a load factor that was a function of pressure was examined as well as the temperature only load factor. The least squares routine was executed using each of the load factors in eqn.(7). From the results presented in Table II and Figs.14 to 16, it appears that the pressure ratio alone is not sufficient to aid in collapsing these three sets of data and the average error for velocity is significant at 5.4%. The temperature only and pressure/temperature load factors provide comparable curve fitting though the average percent difference for the pressure/temperature load factor is slightly better. Both have difficulty with data points whose

velocity is less than or equal to 300 ft/sec when pressure is 15 and 33 psia. It appears that the differences in slope for DS1, DS2, and DS3 (Table I) have a noticeable effect on the ability to collapse the data.

DS14567

DS14567 was curve fit using the temperature only load factor (eqn. 7a) since static pressure was constant. Unmodified, DS14567 spanned a temperature range of 68 F to 250 F and velocities from 135 to 788 ft/sec. The results of curve fitting this data are given in Table III and Fig.17. The average percent error in velocity is high, 4.68%, and very few points actually fall on or near the calculated curve. After reviewing the tabulated results (Appendix B), it was obvious that the largest errors, 8 to 27%, occurred where velocity was less than 250 ft/sec or greater than 700 ft/sec. Based on this observation, data points with velocities less than 250 and greater than 700 were removed and a curve fit made of the modified data. The new curve fit showed a significant decrease in the average percent difference (Table IIIb, Fig. 18) dropping it from 4.68% to 2.88% but some of the end points were still 5 to 7% off. In hopes of further reducing the deviation between measured and predicted velocity values, the effect of limiting the temperature range was also examined. This was done in two parts. The first limited the temperature range but retained the full range of velocities. The second limited the temperature and used the narrowed range of velocity from 250 to 700 ft/sec. In each case several temperature ranges were examined. The results, presented in Table IIIc and d, Fig. 19 and 20 and Appendix B, showed that decreasing the spread of the temperature range only, from about 180 F to 80-90 F, had no significant

impact on improving the relationship between the data and the curve fit. When done in concert with limiting the velocity there is an improvement where the percent error decreases to 2.5% to 3.13% depending on the temperature range involved. Best results occur for temperatures less than 160 F. Overall it appears that it is the limiting of the velocity range that improves the calibration curve fit when it covers a wide range of temperatures.

Comparing the results shown in Tables I, II and III it can be seen that the best correlation between a linear curve fit and the calibration data occurred when the data set for each temperature and pressure combination was curve fit separately. The collapsed curve fit for DS123 shows promise in that if data taking were restricted to conditions where velocity was greater than 300 ft/sec, the average percent error would decrease from 2.75% and 2.84% to 1.5% and 1.7% respectively. For DS14567, the ability to curve fit over such a wide range of temperatures and velocities is marginal, though it is improved somewhat by the limiting of the velocity range as shown in Table III.

One of the assumptions at the start of this investigation was that if a hot-wire or hot-film with greater sensitivity could be used, then perhaps the calibration data would collapse more readily. The sensitivity for this sensor averaged from 1.7mv/ft/sec at 68 F to 1.1mv/ft/sec at 250 F. This is about five to seven times greater than that achieved by McQueen. During McQueen's calibration he achieved a nominal deviation of 5% between his plotted data and the linear curve fit for a temperature range of 74 F to 275 F and velocities of 389 to 996 ft/sec. In this investigation the nominal percent deviation from the linear was 1 to 2% (Table IV) depending on which set of data was used. DS14567mod is

most comparable to McQueen's data covering temperatures from 68 F to 250 F and velocities from 250 to 706 ft/sec. For this the average deviation was 1.11 to 1.19% depending on whether the x or y coordinate is referred to. This is approximately an 80% reduction in average deviation over McQueen's value.

In McQueen's work, the relative goodness of the calibration equation was based on how low the percent deviation from the linear was. That is, do the values of Re^{X_n} and $Nu*Load\ Factor^{X_o}$ calculated from data taken during calibration match the values derived from the calibration (curve fit) equation?

It is important to note that even if the deviation between data based and derived values of Re^{X_n} and $Nu*Load\ Factor^{X_o}$ is low, it doesn't guarantee that the predicted and actual velocity values will agree as well. This can be seen in Table IV where the average percent difference in velocity is 2 to 3 times greater than the average percent deviation from the linear.

VII. Conclusions and Recommendations

Conclusions

This investigation was designed to determine if calibrating a hot-film with greater sensitivity than a tungsten hot-wire would enable the collapsing of several temperature and pressure curves to a single calibration curve. Based on the results obtained, the following conclusions were made:

- 1) Greater sensor sensitivity can significantly reduce the average percent deviation of the data from the linear curve fit. However, as can be seen in Table IV, it is evident that the percent difference between measured and predicted velocity must also be accounted for, since it is often two to three times greater than the percent deviation between predicted and measured x-y coordinates of the calibration curve ($x = Re^{Xn}$, $y = Nu * Load Factor$).
- 2) Best results will be obtained if a calibration equation is developed for each temperature and pressure condition for a given range of velocities.
- 3) The more varied the conditions, the more error is introduced. To make use of a single calibration equation for several conditions requires limiting the velocity range (sometimes severely) and accepting a larger degree of error.

Recommendations

Recommendations are given regarding the application of the hot-wire/hot-film anemometer and for improving the facility for this type of investigation.

1) Since sensor sensitivity seems to improve curve fitting ability, experiment with the TSI PI2.5 sensor which has a higher operating temperature and greater sensitivity than either the platinum or tungsten sensors. See if it will enable the collapse of data for a range of different calibration and test conditions.

2) Study the effects of long term exposure of a hot film sensor to conditions where temperature and velocity vary significantly. See if it causes significant changes in the operating characteristics of the sensor such as the relationship between cold resistance and temperature or operating temperature.

3) To reduce time of calibration and of sensor exposure and to improve control of calibration conditions, design a new calibrator system that has easily adjustable and precise temperature (± 1 F), velocity (± 1 ft/sec), and pressure (± 0.1 psi) control; a constant pressure source; variable nozzle sizes to accommodate different sized sensors; an accurate temperature measuring system; and a means of installing the sensor after the calibrator reaches equilibrium.

4) To enable the use of hot-wires that are extremely susceptible to dirty air, develop a reliable means of filtering the air source, possibly by using an electrostatic filter.

Appendix B

Calculated Data

This section presents the data that was calculated for each curve fit. The measured and derived velocities (eqns.10 and 9, respectively) and the percent difference (eqn.8) between them are presented for each data point. Also listed are Reynolds number and density (lbm/ft^3). The coordinates used to perform the curve fit are given by x and y where $x = \text{Re}^{X_n}$ and $y = \text{Nu} * \text{Load Factor}^{X_o}$. These were calculated using the data presented in Table V. The derived values of x and y are also given and can be used to determine the error between plotted values of x and y and the linear curve fit. The derived values were calculated from the curve fit equation (eqn.13) using y to calculate x_{der} and x to calculate y_{der} .

Table VI presents sensor 1 data for the individual curve fits represented by Fig.7 to 13. Samples of data for sensor 2 are given in Table VII, for an individual curve fit, and Tables XVIII to XX for curve fits of multiple sets of data. Note that the exponents providing the best curve fits for sensor 2 are not necessarily the same as those used for sensor 1.

Tables VIII to X give data for the curve fits of data with different pressures, DS123, using the three different load factors. Tables XI to XVII present the data for the curve fits of the different combinations of data, DS14567, at varying temperatures.

Appendix C

Test Equipment

Table XXI provides a list of all equipment used during this experiment.

TABLE XXI

Test Equipment

| <u>ITEM</u> | <u>MAKE</u> | <u>MODEL</u> | <u>S/N</u> | <u>USE</u> |
|-------------|---|--------------|------------|---|
| 1. | Endevco Power Supply | 4225 | AC12 | Provide power to all but ambient pressure transducers |
| 2. | Endevco Signal Conditioner | 4423 | AB82 | Amplify signal of pressure transducer PT#0 |
| | | | AP02 | Amplify signal of pressure transducer PT#1 |
| | | | AB80 | Amplify signal of pressure transducer PT#2 |
| 3. | Bell & Howell Pressure Transducers | CBC1000-02 | 8986 | PT#0 (0-50 psivg) measures static pressure, P_s |
| | | | 7726 | PT#1 (0-100 psivg) measures source pressure, P_{source} |
| | | | 9294 | PT#2 (0-50 psivg) measures calibrator total pressure, P_0 |
| 4. | TSI Platinum Hot Film Sensor | 1241-10 | J875 | Sensor to measure velocity changes |
| 5. | TSI Intelligent Flow Analyzer | 150 | 144D(Ch3) | Measured resistance and voltage changes due to velocity for Ch1 of sensor |
| | | | 336F(Ch5) | Measured resistance and voltage changes due to velocity for Ch2 of sensor |
| 6. | Tektronix Oscilloscope | 465M | B022081 | Display sensor frequency response |
| 7. | Tektronix Polaroid Camera C-30 Ser | | B016460 | Photograph frequency response signal off of oscilloscope |
| 8. | Hewlett-Packard 3052A Data Acquisition System | HP9845B | 183A03293 | Computer/Thermal Printer |
| | | HP9885M | 1628A12413 | Master Flexible Drive |
| | | | 1629A05355 | Slave Flexible Drive |
| | | HP3455A | 1622A09432 | Digital Voltmeter |
| | | HP3495A | 1428A06961 | Scanner |

TABLE XXI (Cont'd)

Test Equipment

| ITEM | MAKE | MODEL | S/N | USE |
|------|--|--------------------|-------------|---|
| | | HP3437A | | System Voltmeter |
| | | HP9871A | | Impact Printer |
| 9. | HP Dual DC Power Supply | HP9872S HP6205C | 2208A-00632 | Plotter Power for ambient pressure transducer |
| 10. | CEC DC Bridge Balance | 8-108 | 26003 | |
| 11. | MKS Air Calibrator Portable Vacuum Standard | | 44362-1 | Calibrate CEC pressure transducers and pressure gages |
| 12. | Hot Wire Calibrator with VARIAC autotransformer | NONE | NONE | Calibrate hot-wire or hot-films |
| 13. | Pressure Gages | | | |
| | Heise (0-30 psi) | NONE | B43234 | measured static pressure, P_s |
| | Wallace & Tiernan (0-100 psi) | PA145 | PP13097 | measured total pressure, P_o |
| | Wallace & Tiernan (0-30 in Hg) | PA145 | HH10973 | $P_o - P_s$ |

Vita

Captain Denise C. Oka was born on 11 February 1957 in Cincinnati, Ohio. She graduated from Seton High School in 1975 and attended the University of Cincinnati from which she received the degree of Bachelor of Science in Aerospace Engineering in June 1980. Upon graduation, she received a commission in the US Air Force through the ROTC training program and entered active duty in October 1980. Her first assignment was to the Aero Propulsion Laboratory's Ramjet Engine Division where she managed ramjet missile development programs and conducted an inhouse inlet test. In January 1984 she took on the job of Executive Officer for the Laboratory and in November of 1984 became a deputy program manager for the T-46A Simulator Program in ASD's Simulator SPO until entering into the Master of Science program in Aeronautical Engineering at the Air Force Institute of Technology at Wright Patterson AFB, Ohio.

| Abstract (Unclassified) | | | | |
| The possibility of developing a single calibration equation that would be applicable to a wide range of temperatures (68F to 250F), velocities (150 to 800 ft/sec), and pressures (15 to 33 psia) was investigated. A platinum hot-film, with high operating temperature to provide adequate sensitivity to velocity, was calibrated at seven different temperature/pressure conditions. The calibration data was used to calculate velocity, Reynolds number and Nusselt number and a linear least squares curve fit applied to Reynolds number raised to an exponent and Nusselt number times a load factor raised to an exponent. The exponents were chosen, through an iterative process, to provide the best agreement between the data and the curve fit equation. The results indicate that as the range of conditions is allowed to increase, so does the error between measured velocity and velocity | | | | |

derived from the calibration equation. The least deviation in the velocities occurred for curve fits of individual data sets giving an average of 0.8% to 2.5% difference. When several different temperature or several different pressure curves were collapsed to a single curve, the error could be minimized to 2.5% to 3.1% if the velocity range was limited to 300 to 700 ft/sec.
